1 Introduction

MiniZinc \cite{5,7} is a high-level declarative modeling language that has become quite popular in the last few years. One of the main features of MiniZinc is the underlying middle-level constraint language FlatZinc, into which a MiniZinc model, along with a given instance, is translated.

The generality of MiniZinc, and the low-level nature of FlatZinc, which allows it to be implemented efficiently by many solvers, have generated a lot of interest in the CP community around the MiniZinc/FlatZinc tool chain. The flexibility and expressivity of the MiniZinc language is proved by the large variety of modeling constructs that are supported: it includes arrays and sets, along with the basic types (\texttt{int}, \texttt{float}, \texttt{bool}) for parameters (i.e., constants) and decision variables, conditional and loop statements, arithmetic expressions (plus, times, linear equations, inequalities, \ldots{}), boolean expressions (conjunction, disjunction, implication, negation), global constraints (e.g., \texttt{alldifferent}) and set constraints, overloading of built-in and user-defined operations.

Quite a few FlatZinc solvers are publicly available in the research community, but, up to our knowledge, none of them uses meta-heuristics. Among these, GECODE \cite{10} and JACoP \cite{6} are pure constraint programming (CP) solvers, SICStus Prolog \cite{11} has a Prolog engine, MiniSAT(ID) \cite{9} implement propositional logic (SAT) solving techniques, SCIP \cite{1} and Opturion CPX \cite{8} are hybrid solvers: Opturion CPX combines CP and SAT, SCIP is mainly a Mixed Integer Programming (MIP) solver, but it incorporates also a branch-&-cut-&-price and CP framework with SAT-solving features. Currently, the only attempt to design a local search back-end for MiniZinc can be ascribed to Biordal \cite{2} who translate the FlatZinc into a Constraint-Based Local Search model.

In this work, we describe an on-going project consisting in the implementation of a FlatZinc solver based on local search. The solver makes use of the framework \textsc{EasyLocal++} \cite{4}, which provides an abstract implementation of local search techniques. The system is currently at its early stage of development. As such, it implements only integer decision variables and uses a simple “change value to one variable” neighborhood relation. We test the system on the Curriculum-based Course Timetabling problem and compare its results with available FlatZinc solvers. The outcome is quite encouraging as the system, already in the present form, is at the same level of the best available solvers.

2 Local Search Solver for FlatZinc

The overall translation process from FlatZinc to an \textsc{EasyLocal++} solver is illustrated in Figure 1. The local search solver for FlatZinc is based on the new modeling capabilities available in the 3.0 version\footnote{Available at https://bitbucket.org/satt/easylocal-3} of \textsc{EasyLocal++}. The modeling layer allows to define a high-level description of an optimization problem in terms of decision variables and algebraic expressions which are then compiled in an intermediate form that allow an efficient evaluation of local search moves, based only on the modified variables.

A FlatZinc file consists of four parts: \textit{i}) parameter declarations, \textit{ii}) variable declarations, \textit{iii}) constraints, and \textit{iv}) solve goal. Besides the parameters, whose values are directly expanded while parsing...
the FlatZinc file, the other components are translated into EasyLocal::Modeling constructs. In particular, decision variables become variable objects of EASYLOCAL++’s modeling layer whereas intermediate (i.e., introduced) variables and constraints are translated into algebraic expressions. In the case of constraints, the expressions represent a violation measure of the corresponding constraint.

For example, the FlatZinc constraint int_plus(x, y, 5), which states that the sum of \(x\) and \(y\) should be equal to 5, is translated into the corresponding violation expression \(x + y \neq 5\) whose truth value is computed during the search. The solve goal might include an optimization variable that is bound to an objective expression.

Local search upon the EasyLocal::Modeling representation is based on a search space that associates a value to each decision variable and on a neighborhood definition that changes the value of one decision variable at the time. These components are the basis for building an EASYLOCAL++ solver exploiting the different meta-heuristic components and high-level composition strategies made available by the framework.

3 Case Study

We have implemented two MiniZinc models for the Curriculum-based Course Timetabling problem. For the sake of brevity we refer to [3] for the definition of the problem.

The first model considers only the hard constraints and uses two arrays of variables, which assign each lecture to a period and to a room, respectively. The second model includes also all the soft constraints that compose the objective function, and uses several auxiliary variables for the definition of the various components to minimize.

We experimented our solver both on the 21 comp instances of the ITC 2007 challenge and on a group of new artificial instances created using the generator by Leo Lopes [12], which is parameterized upon the total number of lectures and the percentage of room occupation. In detail, we generated 5 instances for each value of the number of lectures in the range \(\{i \cdot 10 | i = 1, \ldots, 13\}\), fixing the percentage of occupation to 70%. We compare our solver with the FlatZinc solvers available in the distribution of MiniZinc (v.1.6): GECODE (v.4.3.3), JA COP (v.4.2.0) and Opturion CPX (v.1.0.2). The results for the first model are reported in Table 1 in terms of percentage of feasible solutions found within the granted computational time (5 minutes on our machine). For our stochastic local search solver, we perform 30 runs for each instance. The average running times of our solver were 6 seconds for the L* family and 24 seconds for the comp family. The table shows that our solver performs at the same level of the best available ones, which however are exact.

For the complete model it is necessary to identify functionally dependent variables, in order to reduce the search space. Experiments on the different strategies for this specific task are under evaluation.
Table 1: Results of different FlatZinc solvers: percentage of feasible solutions found within the timeout.
